**Sampling Errors**

Tables in this appendix present estimates of sampling errors for some of the main variables used in this report, taking into account the complex sample design of the survey.

**Sources of error in surveys**

Survey results are subject to various sources of error. The total error in a survey estimate is the difference between the estimate derived from the sample data collected and the true value for the population. The total error is made up of two main types: systematic and random error.

**Systematic error**

Systematic error occurs when data are consistently biased in a certain way, such that the variation from the true values for the population will not average to zero over repeats of the survey. For example, if a certain section of the population is excluded from the sampling frame, estimates may be biased because non-respondents to the survey have different characteristics to respondents. Another cause of bias may be that interviewers systematically influence responses in one way or another. Substantial efforts have been made to avoid systematic errors, for example, through extensive interviewer training and by weighting the data collected for non-response.

**Random error**

Random error, or bias, is the variation in sample data from the true values for the population, which occurs by chance. This type of error is expected to average to zero over a number of repeats of the survey. Random error may result from sources such as variation in respondents' interpretation of the survey questions, or interviewer variation. Efforts are made to minimise these effects through pilot work and consistent interviewer training.

**Sampling errors**

An important component of random error is sampling error, which arises because the variable estimates are based on a sample rather than a full census of the population. The results obtained for any single sample would be likely to vary slightly from the true values for the population. The difference between the estimates derived from the sample and the true population values is referred to as

the sampling error. The amount of variation can generally be reduced by increasing the size of the sample, and by improving the sample design. Sampling errors have been measured for estimates derived from the General Household Survey (GHS), and these may be used to assess the accuracy of the estimates presented in this report.

## Calculating standard errors

Unlike non-sampling errors, it is possible to estimate the size of sampling error, by calculating the standard error of the survey estimates. The standard error (se) of a percentage  $p$ , based on a simple random sample of size  $n$  is calculated by the formula,

$$se(p)_{srs} = \sqrt{p(100-p)/n}.$$

The GHS uses a multi-stage sample design, which involves both clustering and stratification (see Appendix B). The complexity of the design means that sampling errors calculated on the basis of a simple random sample design will not reflect the true variance in the survey estimates. Clustering can lead to a substantial increase in sampling error if the households or individuals within the primary sampling units (PSUs) are relatively homogenous but the PSUs differ from one another. By contrast, stratification tends to reduce sampling error and is particularly effective when the stratification factor is related to the characteristics of interest on the survey.

Because of the complexity of the GHS sample design, the size of the standard error depends on how the characteristic of interest is spread within and between the PSUs and strata. The method used to calculate the standard errors for the survey takes this into account. It explicitly allows for the fact that the estimated values (percentages and means) are ratios of two survey estimates: the number with the characteristic of interest is the numerator ( $y$ ) and the sample size is the denominator ( $x$ ), both of which are subject to random error.

The standard error of a survey estimate is found by calculating the positive square root of the estimated variance of the ratio. The formula used to estimate the variance of a ratio estimator  $r$  (where  $r = y/x$ ) is shown below.

$$var(r) = \frac{1}{x^2} [var(y) + r^2 var(x) - 2r cov(y,x)]$$

$Var(r)$  is the estimate of the variance of the ratio,  $r$ , expressed in terms of  $var(y)$  and  $var(x)$  which are the estimated variances of  $y$  and  $x$ , and  $cov(y,x)$  which is their estimated covariance. The resulting estimate is only valid if the denominator ( $x$ ) does not vary too greatly. The method compares the differences between totals for adjacent PSUs (postal sectors) in the characteristic of interest. The ordering of PSUs reflects the ranking of postal sectors on the stratifiers used in the sample design.

## Design factors

The design factor, or *deft*, of an estimate  $p$  is the ratio of the complex standard error of  $p$  to the standard error of  $p$  that would have resulted had the survey design been a simple random sample of the same size.

$$deft(p) = \frac{se(p)}{se_{srs}(p)}$$

This is often used to give a broad indication of the effect of the clustering on the reliability of estimates. The size of the design factor varies between survey variables reflecting the

### Sampling Errors

degree to which a characteristic of interest is clustered within PSUs, or is distributed between strata. For a single variable the size of the design factor also varies according to the size of the subgroup on which the estimate is based, and on the distribution of that subgroup between PSUs and strata. Design factors below 1.0 show that the complex sample design improved on the estimate that we would have expected from a simple random sample, probably due to the benefits of stratification. Design factors greater than 1.0 show less reliable estimates than might be gained from a simple random sample, due to the effects of clustering. Design factors equal to 1.0 indicate no difference in the survey design on the reliability of the estimate.

The formula to calculate the standard error of the difference between two percentages for a complex sample design is:

$$se(p_1-p_2)=\sqrt{[deft^2_1(p_1(100-p_1)/n_1)+ deft^2_2 (p_2(100-p_2)/n_2)]}.$$

where  $p_1$  and  $p_2$  are observed percentages for the two sub-samples and  $n_1$  and  $n_2$  are the sub-sample sizes.

### Confidence intervals

The estimate produced from a sample survey will rarely be identical to the population value, but statistical theory allows us to measure its accuracy. A confidence interval can be calculated around the estimated value, which gives a range in which the true value for the population is likely to fall. The standard error measures the precision with which the estimates from the sample approximate to the true population values and is used to construct the confidence interval for each survey estimate.

The 95% confidence intervals have been calculated for each estimated value presented. These are known as such, because if it were possible to repeat the survey under the same conditions a number of times, we would expect 95% of the confidence intervals calculated in this way to contain the true population value for that estimate. When assessing the results of a single survey, it is usual to assume that there is only a 5% chance that the true population value falls outside the 95% confidence interval calculated for each survey estimate. To construct the bounds of the confidence interval, 1.96 times the standard error is subtracted from, and added to, the estimated value, since under a normal distribution, 95% of values lie within 1.96 standard errors of the mean value. The confidence interval is then given by:

$$p \pm 1.96 \times se(p).$$

The 95% confidence interval for the difference between two percentages is given by:

$$(p_1-p_2) \pm 1.96 \times se (p_1-p_2).$$

If this confidence interval includes zero then the observed difference is considered to be a result of chance variation in the sample. If the interval does not include zero then it is unlikely (less than 5% probability) that the observed difference could have occurred by chance.

## Standard errors for the 2005 GHS

The standard errors were calculated on weighted data using STATA<sup>1</sup>. Weighting for different sampling probabilities results in larger sampling errors than for an equal-probability sample without weights. However, weighting which uses population totals to control for differential non-response tends to lead to a reduction in the errors. The method used to calculate the sampling errors correctly allows for the inflation in the sampling errors caused by the first type of weighting but, in treating the second type of weighting in the same way as the first, incorrectly inflates the estimates further. Therefore the standard errors and defts presented are likely to be slight over-estimates. Weighted data were used so that the values of the percentages and means were the same as those in the substantive chapters of the report.

Tables C.1 to C.12 show the standard error, the 95% confidence interval and the deft for selected survey estimates. The tables do not cover all the topics discussed in the report but show a selection of estimates.

For the design factors of household based estimates, one was below 1, one fifth (20%) were below 1.1, just over two fifths (43%) were less than 1.2, and just over two-thirds (70%) of the defts were less than 1.3. There were three cases (10% of all the household-based estimates) where the deft was 1.5 or greater. The higher defts were mostly for tenure and accommodation type (Table C.1) where the effects of clustering lead to a loss of precision compared with that of a simple random sample. The defts that were below 1.1 were in part for the number of persons in the household and household type, indicating that stratification has increased the precision of the sample over a simple random sample for these estimates of household variables.

For the design factors of person based estimates, 2% were below 1, about a tenth (12%) were below 1.1, nearly two-thirds (63%) were less than 1.2, and half (50%) of the defts were less than 1.3. Three per cent of the defts were 1.5 or greater, including many of those for estimates of ethnicity, shown in Table C.6. As well as clustering in the same sectors, people from the same ethnic backgrounds will generally cluster within the same households, and so estimates have high sampling errors and high defts. In contrast, estimates broken down by gender will generally have lower sampling errors because there is often one man and one woman in a household; for example, the estimates of males and females in the population have defts of 0.8 (Table C.4).

## Estimating standard errors for other survey measures

The standard errors of survey measures, which are not presented in the tables and for sample subgroups may be estimated by applying an appropriate value of deft to the sampling error. The choice of an appropriate value of deft will vary according to whether the basic survey measure is included in the tables. Since most deft values are relatively small (1.3 or less) the absolute effect of adjusting sampling errors to take account of the survey's complex design will be small. In most cases it will result in an increase of less than 30% over the standard error assuming a simple random sample. Whether it is considered

### **Sampling Errors**

necessary to use deft or to use the basic estimates of standard errors assuming a simple random sample is a matter of judgement and depends chiefly on the use to which the survey results are to be put.

### **Notes and references**

1. STATA is a statistical analysis software package. For further details of the method of calculation see: Elliot D. A comparison of software for producing sampling errors on social surveys. *SSD Survey Methodology Bulletin* 1999; **44**: 27-36.

## Sampling Errors
